(Dated: March 23, 2010)

We show that electron correlations control the photophysics of defects in SiC through both renormalization of the quasiparticle bandstructure and exciton effects. We consider the carbon vacancy, which is a well-identified defect with two possible excitation channels that involve conduction and valence band states. Corrections to the Kohn-Sham ionization levels are found to strongly depend on the occupation of the defect state. Excitonic effects introduce a red shift of 0.23 eV. The analysis unambigiously re-assigns excitation mechanism at the thresholds in photo-induced paramagnetic resonance measurements [J. Dashdorj et al., J. Appl. Phys. 104, 113707 (2008)].

Optical spectra of semiconductors not only contain the excitations of the perfect bulk crystal but also that of its omnipresent imperfections, such as point defects. Photoluminiscence plays a fundamental role in the experimental characterization and identification of defects [1]. Despite the success of density functional theory (DFT) in explaining the physics of defects in covalent semiconductors [2], this common approach has severe shortcomings: the description of the bonding of the bulk crystal may be insufficient within common approximations for exchange and correlation, like the local spin density approximation (LSDA), the position of defect levels in the band gap is affected by the well-known Kohn-Sham band gap error, and excitations cannot be assessed rigorously. Many-body perturbation theory allows to resolve these issues [3], however, applications to defects are scarce [4] due to computational complexity. The quantitative prediction of absorption spectra of a wide-class of systems from insulators to surfaces, to nanotubes and polymers became tractable only recently by solving the Bethe-Salpeter equations (BSE) and accounting for the G_0W_0 self-energy [3, 5].

In electron paramagnetic resonance (EPR) experiments under illumination [6–8], the positively charged carbon vacancy ($V_{\rm C}^+$) in the 4H polytype of silicon carbide (4H-SiC) was extensively investigated and excitation thresholds were assigned to the defect ionization levels with respect to the neutral defect. The identification of this defect as an EPR-center was established on the basis of the DFT-LSDA ground state calculations [9, 10]. Yet, for the accurate interpretation of the photo-EPR data one has to consider excitation transitions taking into account at least two competing excitation channels: transitions to the neutral state ($V_{\rm C}^0$) as well as to the doubly positive defect ($V_{\rm C}^{2+}$). To assess the values of the ionization levels one has to evaluate the contribution of

excitonic effects that is unknown so far. Knowledge of the ionization levels is pivotal for an understanding of the carrier compensation in high purity semi-insulating SiC [11], in which vacancies are abundant compensation centers, and for the dopant diffusion and defect kinetics [12].

Defect excitations combine the many-body effects in both extended and localized states. The insertion of electrons into defect states invokes on-site correlation due to electron-electron repulsion expressed by the Hubbard U. Defect-to-band transitions involve two particles, the electron and the hole (one in the localized state and the other in the extended state). To self-energy effects this adds excitonic correlation energy of yet unknown size.

The aim of this letter is to investigate many-body effects in the absorption spectrum of a well-identified defect: a carbon vacancy in 4H-SiC. We show that those corrections strongly depend on the occupation of the defect levels, indicating a Hubbard-U which is substantially larger than predicted by DFT-LSDA (1.09 vs. 0.79 eV). Furthermore excitonic effects introduce a sizeable red shift ($\sim 0.23 \,\mathrm{eV}$) varying with the defect charge state. More importantly, the calculated transition energy thresholds for the two competing channels indicate that the current interpretation of photo-EPR spectra [6– 8] based on the assumption of a photoionization via the neutral defect has to be corrected. According to our calculations the ionization to $V_{\rm C}^{2+}$ is the only excitation mechanism at photon energies below 2.3 eV that is responsible for the experimental findings.

The defect absorption spectra and quasiparticle (QP) energies were investigated with the YAMBO-code [13]. The defect in 4H-SiC was represented by a supercell with 288 lattice sites [14]. Among the two inequivalent vacancy sites in 4H-SiC [9] we focus on the experimentally investigated cubic site. In the G_0W_0 and BSE calcu-

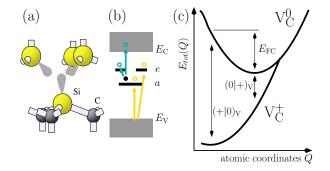

FIG. 1: Carbon vacancy V_C^+ in 4H-SiC (color on-line): (a) geometry – the spin density is indicated, (b) defect levels within the band gap. In the ground state, the a-level is occupied with the paramagnetic electron. Arrows indicate the transitions from the valence band (V) (in orange) and to the conduction band (C) (in green). (c) sketch of the total energy $E_{\text{tot}}(Q)$ of V_C^+ and V_C^0 vs. the atomic coordinates; the QP-energies $(+|0)_V$ and $(0|+)_V$ and the Franck-Condon shift E_{FC} of V_C^0 are indicated (cf. text).

TABLE I: QP-energies $(q|q+1)_{\rm V}$ and $(q|q-1)_{\rm V}$, Franck-Condon shifts $E_{\rm FC}$ and thermal ionization levels (q|q-1) for the relevant charge states of ${\rm V_C}$ in eV. Values are listed as obtained within ${\rm G_0W_0}$ and DFT. First two columns: initial charge state with the occupation of its defect levels. $E_{\rm FC}$ is taken from DFT calculation after electron insertion (cf. text).

		$(q q+1)_{\mathrm{V}}$		(q q -	· 1) _V	$E_{\rm FC}$	(q q-1)	
		G_0W_0	DFT	G_0W_0	DFT		G_0W_0	DFT
$V_{\rm C}^{2+}$	a^0e^0			1.83	1.85	0.29	1.54	1.56
$V_{\rm C}^+$	a^1e^0	1.27	1.24	2.36	2.03	0.83	1.53	1.20
$V_{\rm C}^0$	a^2e^0	0.88	0.72	2.80	2.28	0.21	2.59	2.07
$V_{\rm C}^-$	a^2e^1	1.76	1.39	2.65	2.16	0.41	2.24	1.76

lations spin was taken into account [15]. First we turn to the fundamental band gap of 3C and 4H-SiC. The QP-corrections using the DFT-lattice constant amount to $0.91\,\mathrm{eV}$ and $0.93\,\mathrm{eV}$ respectively, in agreement with earlier G_0W_0 -calculations [16]. Thereby, for the gap of 4H-SiC, we obtain $3.11\,\mathrm{eV}$ (Exp. $3.265\,\mathrm{eV}$ [17]).

Optical absorbtion, as indicated in Fig. 1, involve the defect levels in the band gap, a non-degenerate (a-level) and a two-fold degenerated level (e-level). A (pseudo) Jahn-Teller effect [9] lifts the degeneracy for all charge states except for $V_{\rm C}^{2+}$, however, for $V_{\rm C}^{+}$ the effect is neglegible. Electronic transitions occur predominantly at the fixed geometry of the initial state (Franck-Condon principle). The excitation threshold for transitions between the valence band and the defect states is determined by the QP-energies of the lowest unoccupied defect state (LUMO) $\varepsilon_{\rm LUMO}^{\rm QP}$ and the valence band edge $E_{\rm V}$ and by the electron-hole interaction $E_{\rm eh}$, i.e. $\varepsilon_{\rm LUMO}^{\rm QP} - E_{\rm V} - E_{\rm eh}$. For transitions from the highest occupied defect state (HOMO) to the conduction band with

the band edge $E_{\rm C}$ the threshold is $E_{\rm C} - \varepsilon_{\rm HOMO}^{\rm QP} - E_{\rm eh}$.

Ionization – We now discuss the QP-contribution to the threshold in comparision with the DFT values to discern the many-body corrections within the G_0W_0 . The addition of an electron to the LUMO of the defect in the charge state q (V_C^q) yields V_C^{q-1} . Using E_V as an energy reference for the electron, the energy required for the addition is described by the QP-energy difference $\varepsilon_{\text{LUMO}}^{\text{QP}} - E_{\text{V}}$, which we denote $(q|q-1)_{\text{V}}$. Correspondingly, the removal of an electron from the HOMO of V_C^q , which yields V_{C}^{q+1} , is associated with the energy gain $\varepsilon_{\mathrm{HOMO}}^{\mathrm{QP}} - E_{\mathrm{V}}$ denoted by $(q|q+1)_{\mathrm{V}}$. In DFT, the values are obtained from the total energies. The results are listed in Table I. Consider first V_C^{2+} and V_C^{+} : for the addition of an electron to the unoccupied a-level of V_C^{2+} , $(2+|+)_V$ obtained within G_0W_0 and DFT agree to within $20 \,\mathrm{meV}$. Also, for the electron removal from the a-level of V_C^+ , $(+|2+)_V$ obtained with G_0W_0 matches the DFTresult. Hence, the addition (removal) of an unpaired electron to (from) the a-level is already well described within DFT. Here the QP-correction to the Kohn-Sham level of 0.2 eV (insertion) and -0.23 eV (removal) reflects the screening by valence band electrons and defect resonances. However, for adding a second electron to the a-level exchange and correlation effects beyond the description of the DFT considerably change the mutual repulsion of the two electrons: The G_0W_0 value for $(+|0)_V$ is by 0.30 eV larger than the DFT result. The effective Hubbard interaction $U = (+|0)_{V} - (+|2+)_{V}$ (cf. [18]) among the two electrons in the QP-treatment amounts to $U = 1.09 \,\mathrm{eV}$ instead of the DFT value $U = 0.79 \,\mathrm{eV}$. For the remaining ionization levels, similar changes in the electron-electron repulsion due to the inclusion of exact exchange and the screended Coulomb-interaction in G_0W_0 beyond the DFT description are found.

The thermal ionization level (q|q-1) determines in thermal equilibrium the positions of the Fermi level at which the charge state changes from q to q-1. The level (q|q-1) differs from $(q|q-1)_{V}$ by the Franck-Condon shift, which is the energy gain due to the relaxation of the vacancy after the electron insertion (cf. Fig. 1c). The relaxation leads to an effective electron-electron repulsion U_{eff} smaller than U. To assess (q|q-1) within the G₀W₀-approach, we approximate the Franck-Condon shift $E_{\rm FC}$ by the DFT values. The results are listed in Table I. For V_C^+ , DFT predicts a negative value for U_{eff} [18]. Within DFT we obtain $U_{\text{eff}} = -0.36 \,\text{eV}$. This would imply that the charge state V_C^+ is unstable and in contradiction to the findings [6, 7] should hardly be observable by EPR in thermal equilibrium. However, due to the QPcorrections, the levels (2 + |+) and (+|0) become almost equal (i.e. $U_{\text{eff}} \approx 0$), thus resolving the contradiction. Similarly, a negative-U effect is found for V_C^- . Here, after the QP-correction, U_{eff} remains negative with a value of $-0.35 \, \mathrm{eV}$.

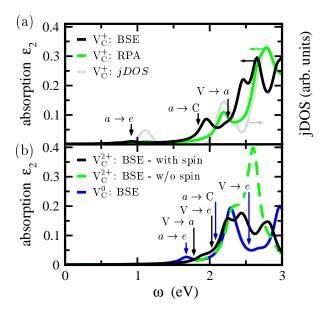

FIG. 2: (color online) Absorption spectra of V_C within G_0W_0 -BSE: (a) for V_C^+ in comparision with the G_0W_0 -RPA spectrum and the joint densisty of states (jDOS) of the transistions with the a-level, (b) for V_C^0 and V_C^{2+} as calculated with spin-polarization and without (for the latter). The onset of excitation channels is indicated. A broadening of $0.1\,\mathrm{eV}$ was used for all spectra.

TABLE II: Ionization (G_0W_0) and excitation (BSE) thresholds as well as experimental data. Also the excitation energy of transition between the a and e level are given. Values are in eV.

Optical properties — Photo-EPR experiements [6–8] were conducted with $V_{\rm C}^+$ as the initial or the final state. The electronic transitions, that quench the paramagnetic state and include the ionization of $V_{\rm C}^+$ into $V_{\rm C}^{2+}$ or $V_{\rm C}^0$, are shown in Fig. 1: (i) excitation from the a-level to the conduction band $(a \to C)$, or (ii) from the valence band to the defect levels a or e ($V \to a$ or $V \to e$). Restoring the EPR-signal of $V_{\rm C}^+$ starts from $V_{\rm C}^{2+}$ or $V_{\rm C}^0$ as initial states by exciting an electron from the valence band to the a-level ($V_{\rm C}^{2+}$) or from the a-level to the conduction band ($V_{\rm C}^0$) and implies the subsequent dissociation of the

electron-hole pair. We calculated absorption spectra for $V_{\rm C}^{2+}$, $V_{\rm C}^{+}$ and, $V_{\rm C}^{0}$ to unravel the relevance of competing channels and to assess the electron-hole coupling. For the latter purpose we compared the spectra with the inclusion of the electron-hole interaction via the BSE and without it, in the random phase approximation (RPA). In the investigated energy range only absorbtion via defect states contributes to spectra due to the indirect band gap. The spectra are shown in Fig. 2 [19]. In Table II, we list the ionization and excitation thresholds. We also calculated RPA spectra, shown in Fig. 3, for the denser $4\times4\times4$ k-point mesh [20] that are converged with respect to the density of extended states. Since such calculations are not feasible for the BSE, corresponding BSE spectra were extrapolated by a convolution ansatz. Spectral broadening due to non-vertical transitions is accounted for by applying a Huang-Rhys factor for the coordinate that connects the geometry of the ground state and the ionized state (broading amounts to $\sim 0.26 \,\mathrm{eV}$).

First we address the spectra of V_C^+ obtained for the special k-point (Fig. 2a). Excitonic effects lead to an almost rigid red shift of the RPA-spectrum by $E_{\rm eh}=0.23\,{\rm eV}.$ The same effect is found also for $V_{\rm C}^{2+}$, and $V_{\rm C}^{0}$ albeit with different values of $E_{\rm eh}$ (cf. Table II). The structure of the RPA-spectrum is dominated by band structure effects. This is demonstrated by comparison with the joint density of states (jDOS) of the transitions involving the a-level, which essentially reproduces the RPA-spectrum. The spectral broadening by Huang-Rys factors, however, reduces these features as seen in Fig. 3. Deviations between the BSE and RPA spectra, besides the red-shift, stem from bright and dark exciton solutions of the BSE due to the spin-dependent electron-hole exchange coupling. The reduction of absorption due to dark exciton states is, however, not obtained in a spin-averaged treatment. This is seen in Fig. 2b, where we compare the BSE-spectra of V_C^{2+} as obtained in the two ways.

The vertical excitation $a \to e$ between the defect levels occur at 0.89 and 1.68 eV for V_C^+ and V_C^0 well below the onset of transitions involving extended states. An important result is that the transitions to the conduction band set in at energies (vertical transitions at 1.61 and 2.02 eV for V_C^+ and V_C^0 , respectively) below the threshold for excitation from the valence band (2.13 eV for V_C^+ and 2.56 eV for V_C^0).

From recent time-resolved photo-EPR experiments [8] cross sections for quenching and restoring of the EPR signal of V_C^+ are available with thresholds at 1.6 and 1.9 eV respectively. Steady state photo-EPR [7] yields values of 1.47 and 1.81 eV, respectively (cf. Table II). The calculated onset for excitation $a \to C$ at 1.61 eV agrees well with the experiments. A rise of the quenching cross section at 2.4 eV [8] should be related to our finding for the onset of the transitions $V \to a$ at 2.16 eV and direct ionization above 2.4 eV that yields V_C^0 . For restoring V_C^+ , however, the excitation of an electron-hole pair with its

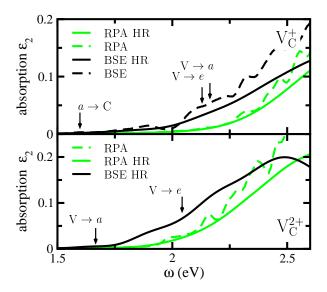

FIG. 3: (color online) Absorption spectra of V_C^+ and V_C^{2+} . G_0W_0 -RPA and extrapolated G_0W_0 -BSE spectra for high k-point density. The effect of Franck-Condon shifts are shown (indicated by the extension HR). A broadening of 0.01 eV was used for the raw G_0W_0 -RPA spectra.

subsequent thermal dissociation or direct ionization is required with thresholds of 1.65 and 1.83 eV, respectively. The comparison with experiment indicates that direct ionization is the relevant process. The present analysis of competing excitations suggests a re-interpretation of the photo-EPR spectra [6–8] in terms of a photoionization of $\rm V_C^+$ via $\rm V_C^{2+}$ instead of $\rm V_C^0$ as considered there. Consequently, the ionization levels deduced from the experiments have to be reassigned correspondingly and corrected for the exciton binding energy.

In summary we conducted GW+BSE full fledge calculations of the photophysics of the carbon vacancy in 4H-SiC. We demonstrate the importance of adding correlation effects at that level, in spite of the fact that the structure is well described at the DFT-level. Charge statedependent corrections include the ionization levels (up to 0.5 eV), the electron-electron repulsion $U (\sim 0.3 \,\mathrm{eV})$ and the electron-hole attraction ($\sim 0.23\,\mathrm{eV}$). This has implications for the analysis of defects in materials, such as oxides, where the correct despription of the bonding is an issue. We showed that ionization of the defect into $V_{\rm C}^{2+}$ and $V_{\rm C}^{0}$ compete. However, for the range of photon energies in which photo-EPR experiment identified thresholds only the former ionization channel is active. Excitation spectra are red shifted by strong excitonic effects. This unambigously rectifies the earlier experimental assignment of transitions and the assessment of ionization levels. These are pivotal for the defect diffusion and for unraveling the mechanisms carrier compensation in semi-insulating SiC and hence for applications.

Rev. B 43, 1993 (1991)], a plane wave basis (energy cut-off of 30 Ry) and, to reduce the defect-defect interaction, the special k-point $(0,0,\frac{1}{4})$ was used. At this k-point the highest valence band lies 60 meV below the valence band edge. Ionization levels in Table I were corrected for this dispersion. Tests for cells with 576 lattice sites confirmed DFT-results.
- [15] G_0W_0 -calculations employ the plasmon pole approximation and include local-field effects in the dielectric function ε and self energy Σ with an energy cut-off of 6 Ry. Convergence was found to be better than $0.1\,\mathrm{eV}$ with

respect to these parameters and the number of empty bands. QP-energies for $V_{\rm C}^+$ and $V_{\rm C}^-$ (with an unpaired electron) and all spectra were evaluated including spin. We employ $\varepsilon(\omega)$ of the defect-free supercell as the low energy transition between the defect levels results in an artifical enhancement of $\varepsilon(\omega=0)$. Tests show that this leads to an underestimation of QP-corrections of about $0.1\,{\rm eV}$. This error reduces with increasing cell size.
